Hybrid Risk Adjustment for Pharmaceutical Benefits

Abstract

This paper analyses the application of hybrid risk adjustment versus either only prospective or only concurrent risk adjustment formulae in the context of funding pharmaceutical benefits for the population of an integrated healthcare delivery organization in Catalonia during years 2002 and 2003. We apply a mixed formula and find that a hybrid risk adjustment model maximizes incentives for efficiency in the provision of low risk individuals by reducing within-group variation of drug expenditures and at the same time eliminates incentives for risk selection for a specific set of high risk individuals through the use of concurrent reimbursement.

Keywords: drug expenditure, hybrid risk-adjustment, morbidity, clinical risk groups.

JEL Classification: I18

1. Introduction

Two major trends regarding pharmaceutical expenditure are currently taking place in developed countries. On one hand, generic drugs introduction contribute to a decrease in unit prices. On the other, new expensive and innovative molecules are being approved by drug regulatory agencies. The final impact of this trend is still unknown, although some initial effects are being observed. For example, concentration of pharmaceutical expenditures among most costly consumers is very high. While US top 10% consumers represented 66% of pharmaceutical expenditures in 1996, in 2003 this proportion decreased slightly to 64%, however, spending per person has more than doubled from \$1,823 to \$3,925 [32].

Such concentration in drug expenditure and in general in health expenditure has strong implications on access and funding of new drugs [17], raises equity concerns [18] and may promote incentives for risk selection [4]. However, beyond these facts there are relevant changes in population morbidity and mortality and some of them are clearly related with health care resources, drugs and medical innovation.

Understanding population patterns of drug consumption, costs and morbidity are less usual since individual data are divided between different sources in fragmented health care systems. There exists, however, recent research showing the link between prescription drug expenditures and population demographic [16].

When citizens are covered under universal coverage and public funding, there is a need for tools to allocate resources for drug expenditures at a population level, which attempt to get value for money. In such situation, understanding morbidity becomes a key issue.

Several initiatives have been developed for setting prescription drugs budgets in primary care, including the addition of incentives [20] and the understanding of its variation [11,12]. However, the prescription drug budget affects all levels of care and not only primary care. The right approach should therefore allow for resource allocation at a population level including all types of drug expenditures.

Under the term risk-adjustment there are several approaches aimed at explaining and predicting costs and utilization of the population using health status data. These models are potentially useful in order to compensate insurers and providers according to the risk they assume as reviewed in the literature [26,10]. In health care payment systems design, any resource allocation has to solve the crucial trade-off between efficiency and selection [19,24]. Risk adjustment has also been used to examine the economic profiling of physicians when claims data are grouped into episodes of care [23]. Although most of risk adjustment studies refer to the US population, there are others referring to European countries as for example Germany [3] or Spain [10] and for other countries as Australia [1]. Too much emphasis on efficiency may promote incentives for selection of patients, benefits (or both). Therefore we have to split the role of risk-adjustment as a mechanism that contributes to understand cost and utilization according to health status, from payment systems that may use the risk-adjustment methodologies as an element in the incentive design. Results in terms of incentives for efficiency and risk selection are sensitive to the type of information used in the payment system and depend on the specific environment. For example, risk selection practices are expected to be less relevant when universal coverage is effective. Thus, while including in the risk adjustment formula only ex ante (prospective) individual information promote incentives for efficiency because health plans can benefit of the savings in the cut of drug expenditures, they also may benefit from selecting patients or benefits. Differently, including ex post (concurrent) information on costs in the payment formula, in what has been called in the literature a risk sharing formula [25,27], reduces the risk assumed by health plans, and therefore the incentives for risk selection, although also the incentives for efficiency. The use of a mixed payment system for total health expenditures started to be explored in the literature in the last decades [2,7,14]. However, there is a relatively new literature addressing specifically the predictability of drug expenditures [29,30,31] and the use of a mixed or hybrid risk adjustment formula with both prospective and concurrent information with the aim of maximizing incentives for efficiency while minimizing incentives for risk selection [6,15]. In a former article [10], we have shown the extent of predictability of pharmaceutical expenditure (and compared our results to other articles in the literature) according to morbidity grouped with the use of the Clinical Risk Groups classification

system under different specification models applying risk adjustment. A recent comparison of the different information systems has been provided by the Society of Actuaries [28]

In this article, we use individual data and analyze the relationship between drug expenditures and morbidity for the population belonging to an integrated healthcare organization covered by the public health system in Catalonia, in the context of the Spanish National Health System. It is important to note that with a universal coverage all patients access health care. However, there potentially exist incentives for a subtle risk selection in which high cost patients might be deviated to different departments within the integrated care organization or to different primary care health areas. Thus, integrated healthcare systems are increasingly searching for tools to allocate budgets and set the right incentives for pharmaceutical expenditure. We consider risk adjustment as a tool able to identify the efficient and inefficient departments of a healthcare organization. Besides, the use of a hybrid formula in the allocation of budgets including concurrent information for patients with specific conditions which tend to concentrate drug expenditures benefits from its higher predictive power and reduces incentives for risk selection by compensating deviations in drug expenditures which are explained by morbidity.

2. Data Sources

We use individual data on prescription drug consumption and morbidity from an integrated healthcare organization, Serveis Sanitaris Integrats del Baix Empordà (SSIBE), in Catalonia. The organization provides publicly funded health services (hospital care, primary care, and long-term care) to the population in the county of Baix Empordà. The providers taken into account are: Palamós Hospital, which has 100 beds for acute patients and 50 for skilled nursing care, and 4 Primary Care Centers. Although citizens may also receive benefits outside the organization, the data on benefits and costs from outside the organization were not available. SSIBE has an information system that integrates clinical activities and costs. The main features that define this information system are: (1) unique identification patient files for all encounters (primary care, specialized care, and inpatient services) and (2) decentralized activity file codified

in ICD-9-CM by clinicians and reviewed by documentalists. The identification of each encounter allows the costs allocation, as in our case, pharmacy costs.

This research uses the following anonymized databases belonging to years 2002 and 2003:

population database, encounters database, and pharmacy database. The first population database was created with the information relative to all the resident population in Baix Empordà: 116,936 citizens. This paper is based only on the analysis of 4 Health Basic Areas (ABS) managed by SSIBE and it refers to morbidity and pharmaceutical expenditure of 87,436 members who were covered during years 2002 and 2003 by the integrated delivery system. Morbidity measurement is performed by the aggregation of the information on codified encounters of the population with the organization (1,290,642 diagnosis and procedures codes). Among the possible risk adjustment systems, in this article we use the *Clinical Risk Groups* (CRGs) (version 1.2B) which allows classifying individuals in mutually exclusive categories while preserving clinical significance, and taking into account co-morbidities and severity levels [13]. From the three different models provided by the CRG software, we use the concurrent model. For each patient we get a unique CRG as well as its corresponding aggregation in ACRG1, ACRG2 and ACRG3. In this paper we describe the population through the highest level of aggregation (ACRG3) and for the estimations we use the second level of aggregation ACRG2 for the classification of patients in morbidity groups. This level of aggregation originally has 176 mutually exclusive categories. However we slightly modify those into 82 mutually exclusive categories fully maintaining its clinical significance by joining patients belonging to different CRGs of the same category but with different levels of severity, in order to avoid over fitting in our estimation because of a very low number of patients in some groups.

Pharmaceutical expenditure information refers both to prescriptions provided by pharmacists publicly financed by Servei Català de Salut (CatSalut) and to prescriptions to inpatients and medical ambulatory supply to ambulatory patients. Therefore, we include in the analysis ambulatory pharmaceutical prescriptions by the doctors belonging to SSIBE and billed by pharmacists, but also primary care, and specialized care prescriptions; and the total pharmaceutical expenditure includes both public financing and private copayment (with a total of 1,206,008 primary care prescriptions that sum up 14,028,102€ in year 2002). This

consumption information incorporates residents as well as other persons that received services from SSIBE. Also it includes resident people with charge to international agreements or people whom they have provisional authentication codes. This means that the total pharmaceutical consumption in the region cannot be fully allocated because part of this consumption does not correspond with the resident's file. Finally, pharmaceuticals consumers in 2002 were 50,280 (57.5 % of the population) with a total individually allocated expenditures of 13,026,913€, from which there is a primary care prescriptions expenditure of 12,091,603€ and a hospital expenditure of 935,310€. Pharmaceutical consumption corresponding to prescriptions beyond SSIBE physicians or OTC drugs was not available.

Table 1 provides the descriptive statistics of the sample. The population is almost equally distributed between males (50.53%) and females (49.47%), and the average pharmaceutical cost has increased from 148.94 euros in 2002 to 182.68 euros in 2003, with 42.50% in 2002 and 38.64% of the population having zero drug expenditure. From table 2, we also observe how most of the patients belong to the healthy condition under the most aggregated classification system (65342 patients representing 74.73% of the sample in 2002 and 63958 patients representing 73.15% of the sample in 2003) while only a few belong to the highest severity group which classifies to the catastrophic condition (125 patients representing 0.14% of the sample in 2002 and 135 patients representing 0.15% of the sample in 2003). From the subgroup of patients with zero drug expenditures, most of them, 95% are classified as healthy (35,421 out of 37,162 in 2002 and 32,397 out of 33,788 in 2003).

3. Study design

This paper estimates prospective, concurrent, and hybrid models using different information sets in order to predict drug expenditures in the subsequent year. Our objective is to examine the predictive power of each model, how well they explain future cost, and provide implications in terms of the application of a hybrid payment formula in the incentives of efficiency and risk selection in the pharmaceutical market. The basic model is provided by:

$$DrugExp_{i,t} = f(demo_{i,t-1}, HS_{i,t-1,t}, \varepsilon_{i,t})$$

Thus, the dependent variable, drug expenditures in year t for individual i , is explained by some independent variables or risk adjusters (individual demographic characteristics and health status information). Demographic information is provided by twelve age-gender cells.

Prospective risk adjustment models predict actual drug expenditure with information on demographic characteristics and clinical status condition in year $t-1$. Differently, concurrent risk adjustment models predict actual drug expenditure using demographic and actual information on clinical status. Hybrid risk adjustment models combine both prospective and concurrent models. Pure prospective models promote incentives for efficiency but they are unable to avoid risk selection. Differently, the use of concurrent reimbursement models, as those based on actual information on cost (risk sharing) or health status (concurrent risk adjustment), presents lower incentives for risk selection because payment is associated to actual information, but incentives for efficiency are also reduced.. The only use of diagnosis-based risk adjustment models does not solve the problem of risk selection because they do not capture within-condition variation even with concurrent information [8]. Therefore, we propose the use of a hybrid risk adjustment model with information on health conditions different to the classification system used in the risk adjustment model, trying to rescue the positive properties of both prospective and concurrent formulae. The hybrid model will promote incentives for efficiency as in the prospective model for most of the population, but will reduce incentives for risk selection for those patients suffering specific health conditions. The reimbursement associated to the second type of patients under the hybrid systems is set as a concurrent payment. In order to divide the population into two parts (one for the prospective payment and the other for the concurrent payment), we utilize the set of 100 verifiable, expensive, predictive conditions (VEP100) already used and presented in the literature [6]. The appropriateness of those conditions stems from the fact that being verifiable (based on objective clinical measures) it is avoided the risk of classifying to this set of patients simply to any expensive patient; being expensive and predictive we select the type of patients that might be at risk of suffering risk selection because of for example, long term treatments.

Because the set of VEP100 conditions in our Spanish sample might be different from that of the U.S. in the literature, we checked its validity by comparing the relative cost weights of the set of

patients with and without VEP100 conditions presented in table 1. As expected, patients suffering at least one of the specific VEP100 conditions systematically present drug expenditures much higher than the rest of patients (603€ versus 92€ in 2002 and 724€ versus 106€ in 2003). Because the problem of risk adjustment models is due to the within-group variation in expected expenditures, we check the distribution of the appearance of VEP100 conditions under the CRG classification system. In table 2 we observe how in relative terms, 96% of healthy patients do not suffer any VEP100 conditions, while increasing the level of severity in the CRGs supposes increase also the proportion of patients with at least one VEP100 condition until around 97% of patients in the catastrophic conditions group. However, it is important to note that in absolute terms about 23% of all patients suffering at least one VEP100 condition (2,165 out of 9,629 in 2002 and 2,473 out of 10,730 in 2003) belong to the healthy group promoting incentives for risk selection. Therefore, we utilize the same VEP100 conditions classification which allows also comparison with other works in the literature. In this article, the specification used in the estimations is the linear regression since although other specifications are considered in an earlier work [10], they do not significantly increase the predictive power while linear regression keeps simplicity in the interpretation for health policy makers. Other alternatives are also being explored in the risk adjustment literature, as the use of regression tree boosting to risk adjust health care cost predictions [21].

4. Main findings

Table 3 presents the R^2 of the different risk adjustment models for predicting drug expenditures. Model 1 only includes demographic information and obtains an R^2 of about 0.09. However, including health status information in the prospective model (models 2), the predictive power increases until an R^2 of 0.21 (only CRG information in model 2a), 0.24 (demographic and CRG information in model 2b) and 0.27 (demographic, CRG information, and presence of at least one VEP100 condition in model 2c). Thus, the higher is the quality of the information used in the prospective model, the better is the predictive power, and including a dummy variable with the presence of a VEP100 condition improves the usual prospective model of the usual risk adjustment model that uses the CRG classification system. Concurrent models 3a to 3c (using

only CRG information, demographic and CRGs, or demographic, CRGs and presence of VEP100 conditions respectively) behaves equally and increases the proportion of explained variance to a highest value of $R^2=0.2893$ (model 3c). When dividing population into two parts depending on the presence of at least one VEP100 condition, the R^2 in the prospective models for patients without those conditions increases and is similar to that of the concurrent model for the whole population, with an R^2 of 0.2769 (model 5c). The reason is that we have eliminated from that sample patients suffering VEP100 conditions (12.27% of the sample), who present a high variation of drug expenditures within CRG categories. At the same time, even in concurrent models, the R^2 of models for those patients with high variation in drug expenditures decreases to 0.2099 (model 4c). The hybrid models take into account the two sub-samples with concurrent information for patients with at least one VEP100 condition and prospective information for patients with no VEP100 condition. In order to calculate the R^2 for hybrid models, we first calculate the total error sum of squares for the combined populations (concurrent and prospective) as the error sum of squares for the concurrent population plus the error sum of squares from the prospective population. At the same time, the corrected total sum of squares is calculated as the sum of squares adjusted for the mean of the overall population. Finally, the R^2 is defined as one minus the ratio of the error sum of squares to the corrected total sum of squares. This methodology has been previously used in the literature [6]. We obtain an R^2 for hybrid models of 0.2263 (model 6c), which is similar to the predictive power of the usual prospective model using demographic and health status information (model 2b) but in which efficiency incentives are higher for provision of pharmaceutical products for 87.73% of the population, and there are no incentives for risk selection for the provision of pharmaceutical products in those patients with VEP100 conditions who are thought to be at risk of suffering risk selection.

In a further attempt to check the validity of the hybrid risk adjustment model, we proceed to develop a sensitivity analysis by changing the criteria for the division of the population. Thus, models 7 to 9 are similar to models 4 to 6, but in which the prospective risk adjustment is assigned for patients suffering less than two VEP100 conditions (96.98%), and the concurrent risk adjustment for patients with at least two VEP100 conditions (3.02%). In this model, the

efficiency incentives remain for a higher proportion of the population, but the predictive power in the prospective model decreases to an R^2 of 0.2199 (model 8c) because we have included patients with high variation in drug expenditures within CRG categories in the sub-sample. Therefore, there still exist incentives for risk selection in this hybrid model for patients suffering one VEP100 condition. Differently, the predictive power of the concurrent model for those patients with more than one VEP100 conditions hugely increases (R^2 of 0.3185 in model 7c), and the R^2 of hybrid models remains in the same level (R^2 of 0.2395 in model 9c versus an R^2 of 0.2263 in model 6c). The interpretation of this result is that the free variation in drug expenditures is specially concentrated in patients suffering one VEP100 conditions because most of them still belong to relatively healthy CRG categories. It is important to note that our R^2 are probably higher than should be expected in other national samples in that all of the providers are from a narrow geographic area, and hence drug expenditure and practice style variations are reduced compared to other greater national samples.

Table 4 presents the predictive ratios for the different risk adjustment models and by different groups of population. In the validating sample, the proportion of population with and without VEP100 conditions slightly varies (12.39% have at least one VEP100 condition and 3.05% have more than one). Results support those from the R^2 presented. All models (prospective, concurrent, and hybrid) benefits from including a dummy variable with the presence of VEP100 conditions. Hybrid models improve the predictive ratio for patients in most of CRG categories, but especially when patients are ordered by deciles of drug expenditures or by presence of VEP100 conditions. Also, the importance of prevalence of clinical conditions is evidenced by the fact that for patients at some CRG categories, prospective models present a better predictive ratio (closer to 1) than concurrent models, which is explained by the timing of the diagnosis during the natural year.

5. Conclusions

Risk adjustment models do not solve completely the tradeoff between efficiency in the provision and risk selection because of the high variation in expenditures within groups. While prospective models promote efficiency, they also are unable to avoid the potential incentives for risk

selection, and concurrent models neither provide incentives for risk selection nor for efficiency. In this paper we follow a hybrid risk adjustment approach in the literature which proposes to divide population into two groups, maximizing incentives for efficiency for those patients not suffering a specific set of conditions, and eliminating incentives for risk selection for those suffering that set of specific health conditions. We utilize the VEP100 set of verifiable, expensive, predictive conditions used in the literature. We include the presence of those conditions as a risk adjuster in the prospective and concurrent models because they explain at some extent the high variation in drug expenditures within groups. Although it is not shown here or elsewhere that this is the optimal way of dividing population, in this paper we show how it improves efficiency incentives in the delivery of pharmaceutical benefits for the population in a county in Catalonia served by an integrated healthcare organization, and eliminates incentives for risk selection for those patients at risk of being deviated to other counties. Risk selection in this specific case is easily verifiable since all individuals are under universal coverage and any denial or transfer to another area would be noticed by the information system of the Catalan Health Service.

The hybrid model associates the concurrent part of the reimbursement formula to fixed amounts according to the verifiable presence of some expensive conditions, and compensates deviations in drug expenditures which are explained by morbidity given its high variation within groups. In such a situation there is a risk of up-coding, although this behavior could be addressed through targeted auditing. In this research we have taken the VEP conditions as given. However, we understand that there is a need to define specific VEP conditions for pharmaceutical expenditure since their impact in pharmaceutical expenditure might be different than that in total health expenditure. Future research is needed towards the application of hybrid risk adjustment models comparable to other studies in the literature and with respect to the search of the optimal set of specific conditions in specific environments that solves the tradeoff between efficiency and selection at a minimal cost. Pharmaceutical expenditure is only one part of total expenditures. Therefore, applications focusing on total expenditures for health benefits package is the next research approach that is needed.
